The nexus between the BRICS alliance and economic growth in South Africa

Abstract

This paper examines the impact of the BRICS alliance on South Africa's economic growth. The study uses time series data from 1980 to 2012 and employs a vector error correction model to achieve its aims. The empirical result reveals that international trade between the BRICS alliance has contributed a lot to economic growth experienced by South Africa. The study also reveals that despite the growth experienced overall in the alliance, South Africa's economic participation is limited due to unfair trade practices amongst the members of the alliance.

Keywords: trade openness, growth, BRICS, unit root, vector error correction model.

JEL Classification: F3, F4, F63, O47.

Introduction

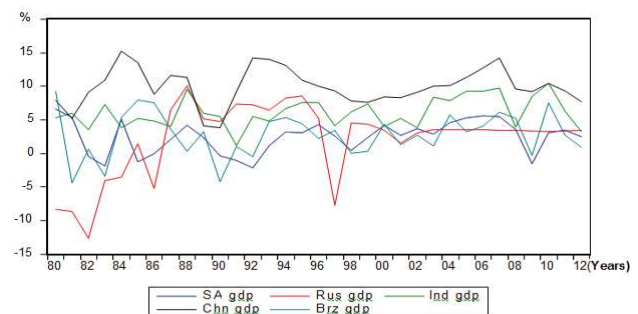

BRICS is the title of an association of emerging national economies namely: Brazil, Russia, India, China and South Africa. These economies represent about 43 percent of the world population, with a combined nominal GDP of over US\$ 14.9 trillion, which is about 25 percent of the world's GDP (WTO, 2013). While BRICS membership presents economic opportunities for South Africa, these are not automatic. Access for South Africa investment into their markets is often difficult. Magroaty (2013) points out that manufacturers complain that the government has not fought very hard on their behalf, and as a result, imports from member countries to South Africa rose 25 percent annually over the past two years (2011 and 2012), while South Africa exports to them rose just 13 percent. Jenkins (2012) argues that this is unpalatable considering that South Africa has higher trade openness than any of the other BRICS nations, yet, they make access to their markets difficult by either imposing trade unfriendly restrictions on South African products and investments. For instance, Jenkins (2012) argues that Chinese competition can affect industrial employment in South Africa through the displacement of domestic production which opts to reduce jobs directly through layoffs and plant closures. Also, indirect impacts where firms facing increased Chinese competition respond by introducing more capital-intensive technologies, or move out of labor-intensive product lines in each industry. This is a big challenge considering that the government has been trying to reduce the unemployment rate.

Therefore, this paper seeks to answer the following questions: Does the BRICS alliance have a positive impact on South Africa economic growth? Beyond political advantages how does this alliance help South Africa to achieve growth?

The paper is structured as follows: Section 1 gives an oversight of the BRICS trade, Section 2 models specification, and the final section concludes the paper.

1. Situational analysis of BRICS trade

Polodoo (2010) points out that notwithstanding the adverse economic and financial shocks that the world faced between 2008 and 2011, China experienced double digit growth rates. The average growth rates were 10.66 percent for China and 6.86 percent for India whilst Brazil, Russia and South Africa experience average growth rates of 2.89 percent, 0.49 percent and 2.66 percent respectively for the period 1980-2012. Growth rate trends are provided in Figure 1.

Source: Knoema (2013).

Fig. 1. GDP trends amongst the BRICS alliance

Jenkins (2012) points out that Brazil is deemed to be one of the fastest growing economies with a large and emerging agriculture, mining, manufacturing and service sectors. It is considered to be the best South American country in terms of economic performance and presently holds a strong status in the world economy. Polodoo (2012) is of the view that Russia is a commodity-driven economy where most foreign currency is earned through fuel and energy, whilst India is a diversified economy consisting of farming, agriculture, industries and a plethora of services. Furthermore, services are considered to be the engine of growth in India, representing more than 50 percent of the country's GDP and employing roughly 30

percent of the labor force (Polodoo, 2012). StatSA (2013) points out that in terms of the balance of trade, South Africa has run a trade surplus with Russia in the last two years, after running trade deficits in 2008 and 2009, whilst, South Africa runs a trade rising deficit of nearly US\$1 billion with Brazil. The country's biggest trade deficit is with China, a figure that reached a high US\$4 billion in the year 2012 (StatSA, 2013).

However, in terms of trade openness all the economics have improved. On the other hand, Polodoo (2012) argues that BRICS economies are mainly export-oriented economies. Brazil, for example, exports transport equipment, iron ore, industrial raw materials, soybeans, footwear, coffee, autos, automotive parts, machinery and imports machinery, electrical and transport equipment, chemical products, automotive parts and electronics. Its main trading partners are the USA, the EU and Argentina.

2. Model specification

Following Mankiw et al. (1992) and Polodoo (2008) an augmented Solow growth model as follows is produced:

$$EG_{it} = \alpha_0 + \beta EG_{it-1} + \lambda Z_{it} + e_{it} \tag{1}$$

The variable *EG* is economic growth rate measured by growth in real GDP of country *i* at time *t*. *EG*_{*i,t-1*} represents growth in the previous year; *Z* is a vector of factors influencing growth; *e*_{*i,t*} is the regression residual which is allowed to vary overtime.

This study estimates the regression model:

$$GDP_{SA} = \beta_0 + \beta_1 \theta TO + \beta_2 \theta EXCH + \beta_3 \theta NFDI + \beta_4 \theta HC + \beta_5 \theta GDCF + \beta_6 \theta GDP_{BRICS} + e \tag{2}$$

2.1. Definition of variables (GDP_{SA}). The variable GDP (South Africa) is economic growth rate for South Africa measured by growth in real GDP of South Africa at time *t* (Polodoo, 2008). It is the dependent variable.

Trade openness (TO). *TO* is the trade openness defined as the sum of exports and imports volume as a percentage of GDP, expressed as an average of the BRICS economy (excluding South Africa) (Knoema, 2013).

Gross domestic fixed capital formation (GDFCF). GDFCF is the gross domestic fixed capital formation from both the government and the private sector of country, it is expressed as an average of the total in BRICS (excluding South Africa) and is in US \$ terms, (Knoema, 2013).

Real exchange rate (EXCH). *EXCH* is an index that describes the relative strength of a currency relative to a basket of other currencies. The benchmark currency basket is a GDP-weighted basket of the major fully convertible currencies of the world, in this study it

would be amongst common regional and international trade partners of the individual BRICS members.

Net foreign direct investment (NFDI). NFDI is the level of net foreign direct investment. The higher the level of FDI, the higher is the growth rate (Smith, 1876). Here it is an average of the total NFDI in BRICS (excluding South Africa) and is in US \$ terms.

Human capital (HC). *HC* is human capital formation proxy by the human development index. Endogenous growth theory postulates that countries which invest heavily in human capital formation enjoy higher growth.

2.2. Data sources. The study uses BRICS annual data for the period 1980-2012. The data was obtained from the Department of Trade and Industry download facility, Statistics South Africa (Stats SA), the Central Intelligence Agency (CIA) countries database, the SARB online download facility, World Bank online download facility and Knoema.

2.3. The expected a priori. Table 1. shows the expected signs and measurement of explanatory variables to be used in the model:

Table. 1. Variables expected signs

Variables	Measured by	Expected sign
<i>TO</i>	(Exports + Imports) Volume as a percentage of GDP	+
<i>GDFCF</i>	GDFCF by government and private sector as a percentage of GDP	+
<i>EXCH</i>	US dollar	+
<i>NFDI</i>	Net Inward and Outward FDI as a percentage of GDP	+
<i>HC</i>	Proxy by the Human development index	+

2.4. Estimation techniques. 2.4.1. Johansen technique based on VAR. The Johansen (1995) test for co-integration is applied in this study. This is because the maximum likelihood framework involved is known to offer better properties than the traditional Engle and Granger approach which is residual based. The following steps are involved when implementing the Johansen technique:

Assuming a set of variables as used in the model such as [GDP (sa); EXCH; TO; GDCF; HCF; GDP (brics) and NFDI] that are in I (1) are thought to be co-integrated. AVAR with *k* lags containing these variables could be set up as:

$$y_t = \beta y_{t-1} + \beta_2 y_{t-2} + \dots + \beta_k y_{t-k} + ut \tag{3}$$

In order to use the Johansen test, the VAR needs to be turned into a vector error correction model (VECM) *yt* of the form:

$$\Delta y_t = \Gamma_1 \Delta y_{t-1} + \dots + \Gamma_{k-1} \Delta y_{t-k} + 1 \Pi_{yt-k} + \Psi D_t + \mu + \epsilon_t, t = 1 \dots T \tag{4}$$

Where Dt are deterministic variables such as dummies and μ is vector of constants. The hypothesis of reduced rank, r , of the long-term impact matrix $\Pi = \alpha\beta'$ is then used to formulate the hypothesis of co-integration. The next step is to establish how many co-integrating vectors exist for each of the relationships. According to Brooks (2002), two test statistics are employed, the λ max statistic and the λ trace statistic.

2.4.1. The vector error correction model (VECM). It is appropriate to estimate an error correction model

if the relevant variables are co-integrated. In a vector error-correction model, the short-term dynamics of the variables in the system are influenced by the deviation from equilibrium:

$$\Delta y_t = \beta_1 \Delta x_t + \beta_2 (y_t - 1 - \gamma x_{t-1}) + v_t \tag{5}$$

The error correction term is given by the implied coefficient on x_{t-1} of one in this term suggests a proportional long run relationship between y and x . Table 2 shows the stationarity tests results.

Table 2. Stationarity results of the augmented Dickey-Fuller test

Note: Values marked with *represent a stationary variable at 5 percent significance level and ** represent a stationary variable at 1 percent significance level.

2.4.2. Tests for co-integration. The Johansen co-integration based on the trace test is shown in Table

3 (a). The trace test shows that they are 2 co-integrated equations.

Table 3 (a). Co-integration rank test (Trace)

Hypothesized No. of CE(s)	Eigen value	Trace statistic	0.05 Critical value	Prob.**
None*	0.822240	164.7584	125.6154	0.0000
Atmost 1*	0.759075	111.2114	95.75366	0.0028

Note: Trace test indicates 2 co-integrating eigen(s) at the 0.05.*denotes rejection of the hypothesis at the 0.05 level. **Mackinnon-Haugh and Michellis (1999) p -values.

Table 3 (b). Co-integration rank test (maximum eigen value)

Hypothesized No of CE(s)	Eigen value	Max-eigen statistic	0.05 Critical value	Prob **
None *	0.822240	53.54700	46.23142	0.0070
Atmost 1*	0.759075	44.12141	40.07757	0.0166

Note: Max-eigen value test indicates 2 co-integrating equations at the 0.05 level;*denotes rejection of the hypothesis at the 0.05 level.

The trace test which is the much stricter test reflected that at least two co-integrating equations exist at 5 percent significance level. The null hypothesis of no co-integrating vectors is rejected since the trace (test) statistic of 164.7584 is greater than the 5 percent critical value of approximately 125.6154. Using the same explanation, the null hypothesis that there is at most 1 co-integrating vector can be rejected since the test statistic of approximately 111.2114 is greater than the 5 percent critical value of about 95.75366. Therefore, the trace statistics specified 2 co-integrating relationship at 5 percent significance level. The maximum eigenvalue test

revealed that there are at least two co-integrating equations at 5 percent significance level. Using the maximum eigenvalue test, the null hypothesis that there is no co-integration at 5 percent significance level is rejected; this is because the eigen value (test) statistic of 53.45700 is greater than the 5 percent critical value of 46.23142. Also the null hypothesis that there is at most 1 co-integrating vector can be rejected since the test statistic of 44.12141 is greater than 40.07757. Therefore, it can be concluded that there are two significant long run relationships between the given variables (using the trace test).

2.5. Diagnostic checks. The fitness of the model using the langrage multiplier (LM) test, followed by the White (Ch-sq) test for heteroskedesticity

and finally the Jarque-Bera for normality test. Diagnostic checks results are shown in Table 4:

Table 4. Diagnostic checks

Test	Null Hypothesis	Statistic value	Probability value
White (Ch-sq)	No conditional heteroskedesticity	459.4495	0.3440
Jarque-Bera	There is a normal distribution	0.717586	0.6985
Langranger Multiplier (LM)	No serial correlation	39.41931	0.8341

Table 4 shows that the test for serial correlation produced an LM statistic of 39.41931 with a probability of 0.834. The LM results suggest that we cannot reject the null hypothesis of no serial correlation. The test for heteroskedesticity using White test with no cross terms produced a Ch-sq

of 459.4495 at a probability of 0.3440. The null hypothesis of no heteroskedesticity or no misspecification will thus not be rejected. Therefore, the model is robust. The null hypothesis for the Jarque-Bera test states that there is a normal distribution.

Table 5. Lag order selection criteria

Lag	Log L	LR	FPE	AIC	SC	HQ
0	-414.3706	NA	1510.536	27.18520	27.50901	27.29075
1	-265.7520	220.5309*	2.655476*	20.75819	23.34862*	21.60261*
2	-211.9311	55.55707	3.320794	20.44717*	25.30422	22.03045

Note: *indicates lag order selected by the criterion, LR: sequential modified LR test statistic (each test at 5 percent level), FPE: Final prediction error, AIC: Akaike information criterion, SC: Schwarz information criterion, HQ: Hanna-Quinn information criterion.

Table 5 shows that overall, criteria selected 1 lag. Therefore a conclusion to adopt 1 lag can be made. Subsequently, the Johansen cointegration test is conducted using 1 lag for the VAR.

us to distinguish between the long and short run impacts of variables so as to establish the extent of influence that changes in independent variables in the BRICS alliance has on South African GDP. Using the outcomes from the co integration test the VECM shall be specified. The VECM results are presented in table 6.

2.6. Vector error correction model (VECM). The discovery of a co-integration equation in the previous section implies that a VECM can be used. This allows

Table 6. Results of the long run co-integration equation

C(7)			0.1089
C(8)			0.3930
C(9)			0.5389

Table 6 shows the long run relationships between GDP (sa) and the dependent variables in the model. The lower panel shows that GDP (sa) is explained by system coefficients C (1) to C (9). However coefficient C (1) of the system is more significant (0.003) in

explaining the longrun relations between GDP (sa) and the dependent variables.

The long run impact of key independent variables on the countries' economic growth as shown by Table 6 is illustrated using equation 9:

$$GDPSA = 0.26 + 0.05EXCH + 1.39GDGCF + 70.5HCF + 0.21NFDI - 0.51TO + 0.25GDP (BRICS). \quad (6)$$

Equation 6 suggests that a percentage increase in θ GDP (BRICS) increases GDP of South Africa by approximately 0.25 (ceteris paribus), possibly as a result of “spill-over effects” that come with globalization. Furthermore, the results suggest that a percentage increase in θ TO in BRICS alliance decreases GDP of South by approximately 0.51 (ceteris paribus), this long run effect implies that goods and technology from the BRICS alliance flood domestic markets in South Africa, thus possibly having lower prices than domestically produced goods as a result of lower production costs and other economies of scale and scope in the other BRICS economies. Measures such as tariff and embargoes on South African products by other BRICS members could also be the cause of this. A percentage increase in θ NFDI in the alliance increases South African GDP by at least 0.21 which could be a derived benefit from the foreign investments made by the rest of the

world in other BRICS economies. A percentage increase in θ HCF increases South African GDP by 70.5, which is the largest impact. This could be as a result of the realization of return on investments in education, health and standards of living in the other BRICS members, thus increasing their economic active population and productivity which in turn benefits South Africa in the long run. Yet a percentage increase in the θ EXCH in the alliance leads to a 0.26 increase of the South African GDP. This could be as a result of the appreciation value gained by the alliance currencies against the US dollar, which then benefits South Africa in the long run.

2.7. Impulse response analysis. Impulse response analysis traces out the responsiveness of the dependent variable in the VAR to shocks to each of the other variables. It shows the sign, magnitude and persistence of real and nominal shocks to economic growth (in this context). Figure 2 shows the impulse responses.

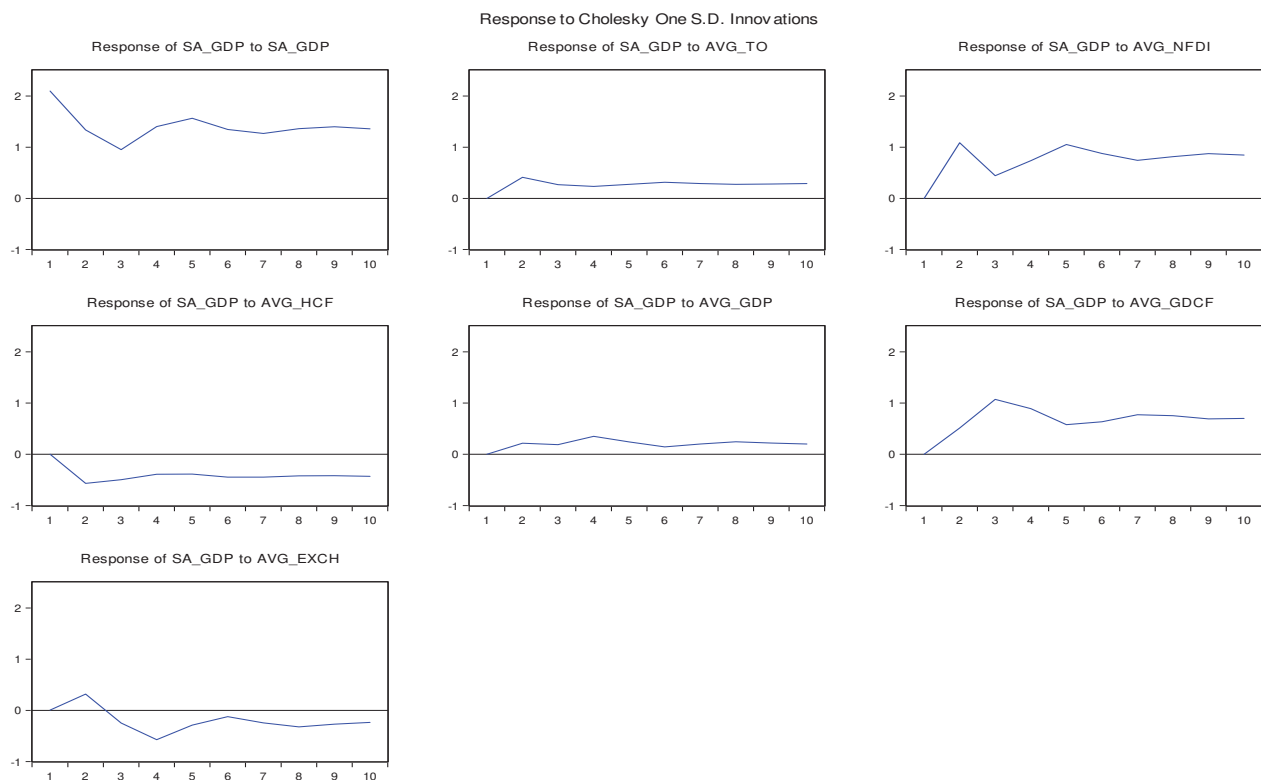

Fig. 2. Impulse responses

Response of: *SA GDP to SA GDP*. There is a positive relationship between GDP South Africa in response to its self into the ten years. However a one standard deviation positive shock of South Africa GDP will cause it self to decrease slightly three years in to the future.

SA GDP to θ TO. A standard deviation positive shock on the average trade openness in BRICS alliance causes a positive increase in South African GDP by about half a unit at least three years into the

future. However, South Africa’s GDP is kept constant into the next seven years.

SA GDP to θ NFDI. One positive standard deviation shock to the average net foreign direct investment within the BRICS alliance causes a sharp increase in South African GDP within the first year as well as a sharp decline after three years. The one unit shock on θ net foreign direct investment will eventually cause an increase in South African GDP after which it shall be slightly varying into the next seven years.

SA GDP to θ HCF. A positive standard deviation shock on the average human capital formation will cause the South African GDP to decrease below the optimal point (0) after the first two years after which it shall be a negative constant variation for the next 8 years. This shows a negative relationship between the average human capital formations in the BRICS alliance with South Africa's economic growth.

SA GDP to θ GDP (BRICS). One standard deviation shock on the average BRICS alliance GDP will cause an insignificant effect on the South African GDP. This is shown by the slight positive fluctuations from the optimal point (0) over the entire ten years. This shows that the BRICS alliance is not stimulating South Africa's economic potential for growth; this could be grounds for policy review.

SA GDP to θ GDCAF. On the other hand, a standard deviation shock on the θ gross domestic capital formation in the BRICS alliance, would cause South Africa GDP to increase gradually within the first three years, after which it decreases gradually between three and five years. Between five and ten years, the shock causes the South Africa GDP to be constant.

SA GDP to θ EXCH. A standard deviation on the θ real effective exchange rates within BRICS alliance causes an initial increase from 0 in two years, however, this cause, the South African GDP to fall sharply within three years. Eventually the shocks on the real effective exchange rates cause the South Africa GDP to fluctuate between slightly above 0 over the next ten years. This shows that increases in θ real effective exchanges rates against the US dollar within BRICS alliance positively impact South African economic growth.

Conclusions and policy recommendations

The long run results suggest that South Africa's trade openness in the alliance has a negative impact on South Africa's economy. This means the BRICS Alli-

ance contribution to SA economic growth is a two sided coin. Overall, the alliance does seem to lift SA growth although the Human Capital Factor is affected in the process. Beyond political gains SA is benefiting from the trade in BRICS, although they are costs attached to it. Theory is not in agreement as to whether trade liberalization or trade protectionism promotes or limits economic growth. Therefore, to improve the South African economy, trade openness in the alliance should be lowered. However, this remedy is only applicable if all the domestic industry is stimulated and the domestic prices are competitive and the infant industries are given optimal terms protecting them against foreign multinationals who already benefit from low production costs, economies of scale and economies of scope. Hence, to increase commercial cooperation, other BRICS members should be lobbied to facilitate market access by effectively addressing hurdles standing in the way of trade development, such as bureaucratic procedures, regulations and standards, import protection, as well as public sector procurement criteria, among others. A significant number of the industries with the highest level of Chinese import penetration are traditional labor intensive sectors such as, textiles and clothing, footwear, leather products and furniture. Chinese competition in these industries therefore is likely to have a severe adverse impact on domestic employment especially of unskilled workers and is likely to increase the unemployment trends and thus increase poverty levels too. One may add by pointing out that government is perceived to be willing to give more incentives to foreign firms than to domestic companies what invest in SA textile, clothing as well as manufacturing firms. Therefore government should remove differential incentives and promote the development of an economy with an attractive climate for investment in general as this will increase both the gross domestic as well as the human capital formation.
